Abstract In this study partial substitute of barley malt by effective use of maize, potato and enset were investigated using saccharomyces cerevisiae. Barley malt is the principal ingredient in the manufacturing of beer and has traditionally been the grain of choice in the brewing industry. However, it is not always economically feasible to brew with 100% malted barley, and at present time breweries are forced to minimize their costs without changing the quality of their beer. Therefore, this study was utilized Maize, Potato and Enset starch as a partial substitute for barley malt and to evaluate some physico-chemical quality attributes of the beer. All the experiments were conducted Dashen Brewery S.C, Ethiopia. Four series of experiments in triplicate involving the starch from the three crops (50%, 62.5% and 75% starch substitute from each) with full barley malt serving as a control was conducted. The major characteristics of the beer (alcohol content & flavor) were evaluated for each of the 50%, 62.5% and 75% substitutes from the three crops with reference to the control beer. The results showed that 75% substitution of barley malt with Maize and Enset starch is promising in the beer production.

Keywords: saccharomyces cerevisiae, amylolytic enzymes, adjuncts, starch

1. Introduction

Beers and beer-like beverages may be prepared from raw cereal grains, malted cereal grains and (historically) bread. The roots of beer production go back much farther to the first agrarian societies [6]. They used a variety of grains called emmer (Triticum dicoccum), which was dehusked and baked to give flat bread. The flat breads were soaked in water and then allowed to ferment spontaneously through the action of wild yeasts. The Babylonians developed the art of brewing further, in which the emmer and barley content as well as the strength of the beer were closely regulated [4].

The Egyptians refined more the art of beer brewing and the legal requirements. They made the grains germinate and eliminated the soaked pieces of bread by sieving. From the seventh century, malting and brewing processes were researched with great experimental zeal, mainly in German monasteries. In the following centuries, brewing and dispensing rights were loaned out to several monasteries. It was also the monks who first used hops as a flavoring agent. Until the sixteenth century, only the spontaneous top fermentation, which occurs at higher temperature, was known; later, bottom fermentation also was discovered [1]. The secondary starch sources being often termed as adjuncts, especially used as a lower cost substitute for malted barley. In this context, obtaining part of the starch by the addition of other starch-containing raw materials (other sources of extract) of brewing adjuncts to partially substitute malt is becoming a standard procedure. Thus, the brewer needs to ensure that wort prepared from mixed grist’s of malt and adjuncts does not diminish the traditionally high quality standards [5]. Starch-rich adjuncts are usually considered non-malt sources of extractable carbohydrate, which typically do not contribute to either enzyme activity or soluble nitrogen [5].

The amount of these adjuncts used is varying widely from 10 to 30% in Europe, to 40 to 50% for some US brewers, to as high as 50 to 75% in certain African countries [2]. However, in certain countries, for example Germany, malt is the only permitted source of fermentable extract because of the German purity law or "Reinheitsgebot" [4].

The increased price of barley malt, low production rate of beer barley due to environmental factors and adulteration of this barley with food barley which is high
2. Over all Process

The production of beverages from malted grain, notably beer, involves many unit operations performed sequentially. The main stages include malting, wort production, fermentation and conditioning (maturation). Each of these operations is followed by a separation stage. In beer making, the wort separation stage which follows mashing is regarded as the most critical and most difficult [3]. Adjuncts can either be added to the cereal cooker, the mash tun or directly to the brew kettle [8].

Cooker mash adjuncts consist of non-gelatinized cereal products (meal, grits, flour, or dry starch) whose starches are in their native forms. A non-gelatinized adjunct needs to be heated in a separate cereal cooker to complete liquefaction since the starch gelatinization temperature of the adjunct is higher than that used for the malt saccharification (starch hydrolysis) temperature [8]. The cooked adjunct is then added directly to the mash in the mash tun. The malt enzymes from the malt mash can be used to hydrolyze the starch from the adjunct, converting it to sugars ready for fermentation [5].

3. Materials and Methods

The materials used in this experiments were:
- Hops from Dashen Brewery,
- Malted barley,
- Yeast of top fermentation (Cervisiae genesis strain) from Dashen Brewery,
- Spring water,
- Potato, Maize and Enset.

Chemicals: All chemicals used in this study were:
- Sulphuric Acid (H₂SO₄) (98%, England),
- Calcium Chloride
- Calcium Sulphate,
- (DNSA),
- Sodium-tartarate,
- Sodium hydroxide
- Phenol
- Sodium acetate
- Filter paper
- Iodine- used for starch test
- Phosphate buffers.

Equipments: the equipments used in this study are listed here under:
- Color comparator
- Kjeldahl apparatus
- Saccharometer
- measuring cylinder
- Oven
- refractometer
- Buhler-Miag
disc miller
Sieve
- Mash bath
digital density meter
- centrifuge
- Vortex and Spectrophotometer.

3.1. Experimental Design and Data Analysis

The three beer varieties including pure barley malt namely barley-maize malt, barley-potato malt, and barley-enset malt were produced in triplicate and evaluated under completely randomized design using CCD using design expert software.

The probability (P-values) values and normal probability plot indicated quadratic polynomial model satisfies ANOVA assumptions and the model was considered to be accurate and reliable for predicting the yield of alcohol (beer) by partial substitute of barley malt with starch crops.

4. Results

Final beers were analysed for a range of key quality parameters: saccharification time, iodine test, alcohol content, original extract, real and apparent degree of fermentation and those were measured directly by instruments are reported. For a normal beer, the parameters were conforming to the quality standards of beer. The values are also in line with the values of the ASBC standard (ASBC, 1999., EBC, 1998).

</table>

For all the three starches (potato, enset, maize) in the three starch-malt compositions (50 %, 62.5 %, and 75 %), the saccharification time was normal (10 to 20 min). This showed that malt usually contains an excess of amylolytic enzymes, so up to 75% of the malt can be replaced with a starch fraction at the mashing step without the need to add enzymes.

5. Conclusion

In this study the use of starches from selected crops (Maize, Enset, and Potato) as partial substitutes for barley malt was found to be promising to develop beer product. The production of beer from the three types of starch sources gave good yield of extract content. Maize was found to produce the highest yield of extract from the three crop types. It is also better in alcohol content, flavor, lautering & saccharification time than others. Enset has been found to be the second important starch source that has a potential application in breweries. It has generally good yield of extract, alcohol content and flavor however performed poor in lautering time at 75% substitute relative to others.

Recommendation

It is recommendable to further study on possibility for improvement and prediction for utilization of starch crops for value-added products like beer for economic and technological development.
